Drop deformation and breakup in a partially filled horizontal rotating cylinder

ANDREW WHITE, CAROLINE PEREIRA, HYAQUINO HYACINTHE, THOMAS WARD, Iowa State University — Drop deformation and breakup due to shear flow has been studied extensively in Couette devices as well as in gravity-driven flows. In these cases shear is generated either by the moving wall or the drop’s motion. For such flows the drop shape remains unperturbed at low capillary number ($Ca$), deforms at moderate $Ca$, and can experience breakup as $Ca \to 1$ and larger. Here single drops of NaOH$_{\text{aq}}$ will be placed in a horizontal cylindrical rotating tank partially filled with vegetable oil resulting in $10^{-2} < Ca < 10^1$. It will be shown that the reactive vegetable oil-NaOH$_{\text{aq}}$ system, where surfactants are produced in situ by saponification, can yield lower minimum surface tensions and faster adsorption than non-reactive surfactant systems. Oil films between the wall and drop as well as drop shape will be observed as rotation rates and NaOH$_{\text{aq}}$ concentration are varied. Results will be presented in the context of previous work on bubble and drop shapes and breakup.
