Energy and water vapor transport in a turbulent stratified environment

LUCA GALLANA, Politecnico di Torino, FRANCESCA DE SANTI, MICHELE IOVIENO, Politecnico di Torino, DIMEAS, RENZO RICHIARDONE, Università degli Studi di Torino, DANIELA TORDELLA, Politecnico di Torino, DIMEAS — We present direct numerical simulations about the transport of kinetic energy and unsaturated water vapor across a thin layer which separates two decaying turbulent flows with different energy. This interface lies in a shearless stratified environment modeled by means of Boussinesq’s approximation. Water vapor is treated as a passive scalar (Kumar et al. 2014). Initial conditions have \( Fr^2 \) between 0.64 and 64 (stable case) and between -3.2 and -19 (unstable case) and \( Re_\lambda = 250 \). Dry air is in the lower half of the domain and has a higher turbulent energy, seven times higher than the energy of moist air in the upper half. In the early stage of evolution, as long as \(|Fr^2| > 1\), stratification plays a minor role and the flows follows closely neutral stratification mixing. As the buoyancy terms grows, \( Fr^2 \sim O(1)\), the mixing process deeply changes. A stable stratification generates a separation layer which blocks the entrainment of dry air into the moist one, characterized by a relative increment of the turbulent dissipation rate compared to the local turbulent energy. On the contrary, an unstable stratification slightly enhances the entrainment. Growth-decay of energy and mixing layer thickness are discussed and compared with laboratory and numerical experiments.
