Measurement of dipion azimuthal angular correlations intransversely polarized pp collisions at $\sqrt{s} = 62.4$ GeV in Center of Mass using PHENIX detector at RHIC.\textsuperscript{1} NATHAN MEANS, SUNY Stony Brook, PHENIX COLLABORATION — It has been recently suggested that observation of azimuthal asymmetry in back-to-back jets produced in single transverse polarized pp collisions at RHIC would be a direct evidence for non-zero transverse momentum in the nucleon [Boer and Vogelsang]. The connection of this transverse momentum and the orbital angular momentum of the partons in the nucleons has also been discussed in the literature. PHENIX is a multipurpose detector at RHIC with electromagnetic calorimetry ($d\phi \times d\eta = 0.01 \times 0.01$) in the diagonally opposite $d\phi = \pi/2$ regions around the horizontal plane, and a pseudorapidity range of $|\eta| = 0.35$. This enables PHENIX excellent measurement of $\pi^0$'s which may be the remnants of produced the jet in pp collisions. In the recently finished run (RHIC Run-6) we added the Muon Piston Calorimeter (MPC), a new PbWO$_4$ crystal calorimeter, which covers the pseudorapidity range 3.1 to 3.6 and $\phi = 2\pi$. With these two EM calorimeters we plan to make the back-to-back angular correlation measurements in double pion production from the transverse spin proton-proton collisions. About 20 nb$^{-1}$ of data with an average beam polarization of 57% were collected in Run-6. I will present the status of this analysis from Run-6 data.
