BATTAGLIA, University of Wisconsin - Madison, AND THE NSTX TEAM — The resistive wall mode (RWM) can be stabilized by maintaining the plasma toroidal rotation frequency ($\omega_\phi$) above a critical rotation frequency ($\Omega_{\text{crit}}$). Recent experiments on NSTX seek to determine $\Omega_{\text{crit}}$ and rotation profile effects through actively braking plasma rotation by the application of external magnetic fields. Results from these experiments indicate that maintaining $\omega_\phi$ at the $q = 2$ surface above $\omega_A/4q^2$ is a necessary condition for RWM stability where $\omega_A$ is the local Alven frequency. This result is in agreement with a theoretical model derived from a drift-kinetic energy principle. Similarity experiments with DIII-D are being performed to examine the aspect ratio dependence of the $\Omega_{\text{crit}}$ scaling. When $\omega_\phi$ at the $q = 2$ surface drops below $\Omega_{\text{crit}}$, the growth of internal kink/ballooning modes can prevent the RWM from terminating the discharge. A small beta collapse which drops $\Omega_{\text{crit}}$, accompanies this mode growth allowing a recovery of RWM rotational stabilization while maintaining $\beta_N > \beta_{N-\text{wall}}$.
