Investigation of Edge Localized Modes in Alcator C-Mod

J.L. TERRY, MIT-PSFC

Characteristics of discrete ELMs produced in Alcator C-Mod discharges of low edge collisionality and high triangularity are examined. These discharges have high values for central $T_e$ and $n_e$ (reaching 4.5 keV and $2 \times 10^{20}$ m$^{-3}$ respectively) and good confinement, consistent with ITER98y2 ELMy H-mode scaling. Pedestal temperature heights reach 0.9 keV at densities above $1 \times 10^{20}$ m$^{-3}$. Studies of the stability of the pedestal profiles to peeling/ballooning modes will be presented. The energy lost per ELM from the H-mode pedestal is $\sim$10-20% of the pedestal energy. These ELMs exhibit relatively long-lived precursor oscillations, often with two modes of intermediate ($n \sim 10$) toroidal mode number present. At the ELM “crash” a high frequency ($\sim 0.5$ MHz), short-lived magnetic oscillation is initiated, and multiple plasma filament structures are expelled into the Scrape-Off-Layer. The initial ELM filaments, “primaries”, are large perturbations to the SOL. The perturbation increases the local $D_\alpha$ emission by factors ranging from 1.5 (just outside the LCFS) to $\sim$100. In the outboard midplane region the primary filaments have radial extents of 0.5-1 cm and typical radial propagation velocities of 1-2 km/s. The poloidal extent of the filaments is greater than the 4.5 cm diagnostic field-of-view. The initial filaments are followed (at intervals of $\sim 100 \mu$s) by multiple, less perturbing “secondary” filaments. The radial dynamics of the ELM are also studied at the inboard midplane. The perturbation on the inboard edge appears to be a rapid profile relaxation and recovery. The onset of the inboard profile relaxation is sometimes observed to occur before filaments are seen on the outboard side.
