Size Dependence of the Static Polarizabilities and Absorption Spectra of Gold Clusters

SERDAR OGUT, JUAN CARLOS IDROBO\textsuperscript{1}, University of Illinois at Chicago, JINLAN WANG, JULIUS JELLINEK\textsuperscript{2}, Chemistry Division, Argonne National Laboratory — We present results for static polarizabilities and absorption spectra for ground state structures of Au\textsubscript{n}, \(n = 2 - 14, 20\), clusters calculated within static and time-dependent density functional theory. The static polarizabilities of the clusters with less than 14 atoms exhibit even-odd oscillations. The polarizabilities of Au\textsubscript{14} and Au\textsubscript{20} are noticeably lower. This change in the behavior of static polarizability is correlated with the transition from two-dimensional to three-dimensional structures at \(n = 14\). The \(d\) electrons have a large effect on the optical spectra as they quench the oscillator strengths significantly and are heavily involved in low-energy excitations. The calculated spectra are compared with available experimental data and spectra obtained for Ag\textsubscript{n} clusters.\textsuperscript{3}
