Contact Percolation in Dense Granular Flow

FUPING ZHOU, ExxonMobil Research and Engineering Company, DENIZ ERTAS, ExxonMobil Research and Engineering — Steady-state rheology of spheres are studied in the dense flow regime with three-dimensional molecular dynamics simulations in two different geometries: Simple shear flow and gravity-driven chute flow. The same set of constitutive equations, which are only a function of the local dimensionless strain rate, \( I \), are found to characterize bulk macroscopic observables such as density, internal Coulomb coefficient and scaled velocity fluctuations in both cases. A transition has been identified at a finite (non-universal) value of \( I = I_c \), corresponding to the percolation transition of the instantaneous contact network. For \( I < I_c \), an infinite contact network spans the system. The flow dilates and the internal Coulomb coefficient increases with increasing \( I \). For \( I > I_c \), the instantaneous contact network is broken into finite clusters. The system dilates further with increasing \( I \) while the internal Coulomb coefficient becomes independent of \( I \), resulting in a maximum tilt angle for steady chute flow. Scaled velocity fluctuations exhibit power-law dependence on \( I \) on both sides of \( I_c \), with a minimum at the transition. The transition is distinct from the “jamming” transition at \( I = 0 \) associated with the rigidity percolation of the contact network.
