Abstract for an Invited Paper
for the DPP06 Meeting of
the American Physical Society

Quantitative experiments with electrons in a positively-charged particle beam[1]

ARTHUR MOLVIK, Lawrence Livermore National Laboratory and Heavy-Ion Fusion Science Virtual National Laboratory

Intense ion beams are an extreme example of non-neutral plasma. We use experiments and simulations to study the complex interactions between beam ions and (unwanted) electrons. (Such electron clouds limit the performance of many accelerators.) The detailed, self-consistent simulations use the 3-D Particle-In-Cell code WARP, with the addition of beam-transport fields, and electron and gas generation and transport, to compute unexpectedly rich behavior [1], much of which is confirmed experimentally. In magnetic-field-free regions, we observe a variety of beam-surface interaction phenomena: electron emission, gas desorption, ionization of gas, and virtual cathode fluctuations. In a quadrupole magnetic field, ion and dense electron plasmas interact to produce multi-kV oscillations in the electron plasma and distortions of the beam velocity space distribution, without becoming homogenous or locally neutral. We developed a variety of methods to measure and control electron and gas clouds in ion beams. Parameters we measure include: beam potential profiles and time dependence, total and local electron production and loss, electron line-charge density [2], gas pressure within the beam, electron accumulation, and electron trapping depth. Control methods include surface treatments to reduce electron and gas emission, and techniques to remove electrons from the beam.
