Weak phase stiffess and nature of the quantum critical point in underdoped cuprates[1] WEI KU, YUCEL YILDIRIM[2], Brookhaven National Laboratory — We demonstrate that the zero-temperature superconducting phase diagram of underdoped cuprates can be quantitatively understood in the strong binding limit, using only the experimental spectral function of the "normal" pseudo-gap phase without any free parameter. In the prototypical $(La_{1-x}Sr_x)_2CuO_4$, a kinetics-driven d-wave superconductivity is obtained above the critical doping $\delta_c \sim 5.2\%$, below which complete loss of superfluidity results from local quantum fluctuation involving local p-wave pairs. Near the critical doping, a enormous mass enhancement of the local pairs is found responsible for the observed rapid decrease of phase stiffness. Finally, a striking mass divergence is predicted at δ_c that dictates the occurrence of the observed quantum critical point and the sudden suppression of the Nernst effects in the nearby region.
